Introducing Positivism

Positivism is a set of philosophical approaches that seeks to apply scientific principles and methods, drawn from the natural and hard sciences, to social phenomena in order to explain them. Auguste Comte (1798–1857) is widely acknowledged as the father of positivism. He argued that social research prior to the nineteenth century was speculative, emotive and romantic and as a result it lacked rigour and analytical reasoning. Unwin (1992) details that Comte used the term ‘positive’ to prioritize the actual, the certain, the exact, the useful, the organic, and the relative. In other words, he posited that it is more useful to concentrate on facts and truths – real, empirically observable phenomena and their interrelationships – than on the imaginary, the speculative, the undecided, the imprecise. What Comte demanded was the objective collection of data through common methods of observation (that could be replicated) and the formulation of theories which could be tested (rather than as with empiricism where observations are presented as fact). Such testing would be systematic and rigorous and would seek to develop laws that would explain and predict human behaviour. As such, Comte rejected metaphysical (concerned with meanings, beliefs and experiences) and normative (ethical and moral) questions as they could not be answered scientifically. Like with most other ‘isms’ and ‘ologies’ there are various different forms of positivism. The two most commonly discussed are logical positivism based on verification and critical rationalism based on falsification.

Logical positivism was developed by the Vienna Circle (a loose collection of social scientists and philosophers) in the 1920s and 1930s. Like Comte, they posited that the scientific method used in the traditional sciences could be applied directly to social issues – that is, social behaviour could be measured, modelled and explained through the development of scientific laws in the same way that natural phenomena are examined. Such a view is called naturalism and is underpinned by a set of six assumptions as detailed by Johnston (1986: 27–8):

1. That events which occur within a society, or which involve human decision-making, have a determinate cause that is identifiable and verifiable.
2. That decision-making is the result of the operation of a set of laws, to which individuals conform.
3. That there is an objective world, compromising individual behaviour and that the results of that behaviour which can be observed and recorded in an objective manner, on universally agreed criteria.
4. That scientists are disinterested observers, able to stand outside their subject matter and observe and record its features in a neutral way, without in any respect changing those features by their procedures, and able to reach dispassionate conclusions about it, which can be verified by other observers.

The Vienna Circle’s work, however, analytical precision. As such, the scientific principles of social behaviour are laws verified (theories explain) mode of measures centred on the statement of facts (distance, wage). The statistical testing variables as a meaningful laws. Because known facts that a large populations (possible to test and large sample sizes). It is employed, where hypotheses are, cases where the definitive hypotheses, the theoretical hypotheses set, and cumulative process theories are extended and systematic incorporation of revision and resetting of samples are often unnecessary.
5 That, as in the study of inanimate matter, there is a structure to human society (an organic whole) which changes in determinate ways, according to the observable laws.

6 That the application of laws and theories of positivist social science can be used to alter societies, again in determinate ways, either by changing the laws which operate in particular circumstances or by changing the circumstances in which the laws will operate.

The Vienna Circle significantly extended Comte’s work, however, by formulating rigorous analytical procedures centred on verification. As such, they sought to define precise scientific principles and methods by which social behaviour could be measured and social laws verified (the extent to which scientific theories explained objective reality). The mode of measurement they advocated was one centred on the precise quantitative measurement of facts (e.g. heights, weights, time, distance, wage). These measurements allowed the statistical testing of relationships between variables as a means to test (verify) explanatory laws. Because the method focuses on known facts that are easily collected across large populations (e.g. using the census) it is possible to test and verify laws against very large sample sizes. Here, a deductive approach is employed, wherein a theory is formulated and hypotheses are set and then tested. In cases where the data do not support the hypotheses, the theory can be modified, new hypotheses set, and the data reanalysed. A cumulative process is thus adopted, wherein theories are extended and built up in a structured and systematic manner through the incorporation of new findings and the rejection and resetting of hypotheses. Given that samples are often not perfect, complete verification is understood to be impossible, and logical positivism thus deals with weakly verified statements understood in terms of probabilities (the statistical likelihood of occurrence) that it aims to strengthen (Johnston, 1986). By increasing the strength of the probability that a relationship did not occur by chance and is potentially causal, hypotheses can be tested and theories deductively constructed. In this way, logical positivism provides a method for gaining objective knowledge about the world. Objectivity through the independence of scientists is maintained through conformity to the following five premises (Mulkay, 1975, cited in Johnston, 1986: 17-18):

1 Originality – their aim is to advance knowledge by the discovery of new knowledge.
2 Communalitv – all knowledge is shared, with its provenance fully recognized.
3 Disinterestedness – scientists are interested in knowledge for its own sake, and their only reward is the satisfaction that they have advanced understanding.
4 Universalism – judgements are on academic grounds only, and incorporate no reflections on the individuals concerned.
5 Organized scepticism – knowledge is advanced by constructive criticism.

In contrast to Comte, the Vienna Circle accepted that some statements could be verified without recourse to experience, making a distinction between analytical statements and synthetic statements. Analytical statements are a priori propositions whose truth is guaranteed by their internal definitions (Gregory, 1986a). Such analytical statements are common in the formal sciences and mathematics, where questions are often solved in a purely theoretic form long before they can be empirically tested. Indeed, theoretical physics almost exclusively seeks to provide solutions (based on known laws and properties) to problems that remain impossible to empirically test (see for example Steve Hawking’s A Brief History of Time). Synthetic
statements are propositions whose truth needs to be established through empirical testing because they lack internal definition and are complex. In addition, the Vienna Circle forwarded science (that is the claim that the positivist method is the only valid and reliable way of obtaining knowledge, and all other methods are meaningless because they do not produce knowledge that can be verified) and a narrowly defined scientific politics that argued that positivism offers the only means of providing rational solutions to all problems (Johnston, 1986).

Critical rationalism was developed in response to logical positivism and challenges its focus on verification. Forwarded by Karl Popper, it contends that the truth of a law depends not on the number of times it is experimentally observed or verified, but rather on whether it can be falsified (Chalmers, 1982). Here it is argued that rather than trying to provide a weight of confirmatory evidence, scientific validation should proceed by identifying exceptions that undermine a theory. If no exceptions can be found then a theory can be said to have been corroborated. The critique of such an approach is that a theory can never be fully validated as a yet unidentified exception might still be awaiting discovery (Gregory, 1986b). While many geographers would profess to adopting a critical rationalist approach based on falsification, in practice they tend to employ verification, seeking to explain away exceptions or residuals by recourse to statistics based on probability, rather than rejecting a hypothesis outright. A variety of other versions of positivism have been proposed and contemporary positivist philosophy significantly extends the work of the Vienna Circle. That said, debates in geography draw on these older forms of positivism, mainly because positivist geography itself rarely engages in any deep or meaningful dialogue with philosophy and as such its underpinnings have not been advanced with regard to new forms of positivism.

Development and Use of Positivism in Human Geography

Positivism is one of the unrecognised, ‘hidden’ philosophical perspectives which guides the work of many geographers ... [It remains hidden] in the sense that those who adhere to many of its central tenets rarely describe themselves as positivists ...

While many boldly carry the banner of their chosen philosophy, the name of positivism is rarely seen or heard in the works of geographers who give assent to its basic principles. (Hill, 1981: 43)

Until the 1950s, geography as a discipline was essentially descriptive in nature, examining patterns and processes, often on a regional basis, in order to try to understand particular places. From the early 1950s, a number of geographers started to argue that geographical research needed to become more scientific in its method, seeking the underlying laws that explained spatial patterns and processes. For example, Frederick Schaefer, in a paper often cited as the key catalyst for the adoption of scientific method in human geography, argued that ‘geography has to be conceived as the science concerned with the formulation of the laws governing the spatial distribution of certain features on the surface of the earth’ (1953: 227). In effect Schaefer drew on the arguments of logical positivism to contend that geography should seek to identify laws, challenging the exceptionalist claims of geographers such as Hartshorne (1939) that geography and its method was unique within the social sciences. In other words, geography should shift from an ideographic discipline (fact gathering) focusing on regions and places to a nomothetic (law producing) science focused on spatial arrangement.

The principal concern of the early advocates of geography as a spatial science was that geographical enquiry up to that point was largely unsystematic. Geographers were accounts of the working facts as evidence. The problem was that between causal or spurious (not, for example, environment suggested that explicitly influence (e.g. high am

do the early advoc- tial science was that to that point was largely unsystematic and analytically naive. Geographers were developing empiricist accounts of the world by simply accumulating facts as evidence for generalist theories. The problem with such empiricist endeavours was that they did not distinguish between causal correlations and accidental or spurious (non-causal) associations. For example, environmental determinist accounts suggested that environmental conditions explicitly influenced society in a causal fashion (e.g. high ambient temperatures caused underdevelopment in tropical countries by inducing idleness among local residents) (Hubbard et al., 2002). Moreover, such accounts committed ecological fallacies, that is ascribing aggregate observations to all cases within an area. However, just because two things are observed in the same place at the same time does not mean that one caused the other or that they apply universally. These patterns need to be tested scientifically. Indeed, most people now accept that ambient temperature may influence human behaviour, but it does not determine it, and it has little or no effect on levels of development. For geographers such as Schaefer, geography as a discipline would gain real utility, and by association respectability within the academy, only if it became more scientific. Scientific method would provide validity and credibility to geographic study and it would provide a shared language for uniting human and physical geography.

Quantitative revolution

What followed was the so-called quantitative revolution wherein the underlying principles and practices of geography were transformed (Burton, 1963), with description replaced with explanation, individual understandings with general laws, and interpretation with prediction (Urwin, 1992). In order to employ a scientific method, to transform human geography into a scientific discipline concerned with the identification of geographical laws, a number of geographers started to use statistical techniques (particularly inferential statistics, concerned with measuring the probability of a relationship occurring by chance) to analyse quantitative data. Quantitative data were seen as factual, as objectively and systematically measured. They were therefore universal in nature, free of the subjective bias of the measurer and analyst. By statistically analysing and modelling these data, geographers hoped to be able to identify universal laws that would explain spatial patterns and processes, and also provide a basis for predicting future patterns and identifying ways to intervene constructively in the world (e.g. altering policy to engender change). So, just as physics and chemistry tried to determine the general laws of the physical world, geographers adopted a naturalist position (a belief in the equivalence of method between social and natural sciences) to try to determine the spatial laws of human activity.

This transformation in theory and praxis led to a whole variety of different types of laws, most of which did not pretend to be the universal law as portrayed by many critics. For example, Colledge and Armedee (1968, summarized in Johnston, 1991: 76) detailed four types of law being developed in human geography: Cross-sectional laws describe functional relationships (as between two maps) but show no causal connection, although they may suggest one. Equilibrium laws state what will be observed if certain criteria are met. ... Dynamic laws incorporate notions of change, with the alteration of one variable being followed by (and perhaps causing) an alteration in another. ... Finally statistical laws ... are probability statements of B happening, given that A exists' (the first three laws might be deterministic or statistical).

The aim, in short, was to create a scientific geography, with standards of precision, rigour and accuracy equivalent to other sciences (Wilson, 1972). However, as Hill (1981) notes, given that spatial science borrowed the idea of
BOX 2.1 SPATIAL MODELS AND LAWS

Throughout the late 1950s and the 1960s a whole plethora of geographical models and laws, based on scientific analysis of quantitative data and taking the form of mathematical formulae, were developed using a hypoductive approach. For example, early quantitative geographers tried to find a formula that adequately modelled the interaction of people between places. One of these was Isard et al.'s (1960, detailed in Haggett, 1985: 40) inverse-distance gravity model:

\[ M_{ij} = \left( \frac{P_i}{d_{ij}} \right) f(Z) \]

where \( M_{ij} \) is the interaction between centres \( i \) and \( j \), \( P_i \) is a measure of the mass of centre \( i \), \( d_{ij} \) is a measure of the distance separating \( i \) and \( j \), and \( f(Z) \) is a function of \( Z \), where \( Z \) measures the attractive force of destination \( i \). This advanced earlier models that did not take into account how 'attractive' each location might be in relation to others (for example, in climate or amenities).

While scientific method largely without conscious reflection on its philosophical underpinnings it is perhaps better to term it positivistic rather than positivist. Certainly, many positivistic geographers (most of whom would prefer to adopt the label quantitative or statistical geographers) would balk at the scientism and scientistic politics of logical positivism, though they would see the scientific method as the most sensible and robust (rather than the only) approach to geographical enquiry (see also Chapter 22).

As with all 'revolutions', certain key sites and people were instrumental in pushing and developing the emerging quantitative geography. In the US, geographers such as William Garrison at Washington State, Harold McCarty at Iowa State and A.H. Robinson at Wisconsin trained a generation of graduate students who became faculty elsewhere, where in turn they propagated their ideas (Johnston, 1991). In the UK, Peter Haggett at Bristol and later Cambridge was a key influence (along with physical geographer Richard Chorley). Indeed Haggett's book *Locational Analysis in Human Geography* (1965) was an important text that helped to strengthen the case for quantitative geography. Such was the pace of adoption that by 1963 Burden had already declared that the revolution was over and quantitative geography was now part of the mainstream. That said, it is important to note that not all geographers were enthusiastic converts to what was increasingly called spatial science, and many continued to practise and teach other forms of geographical enquiry (Johnston, 1991; Hubbard et al., 2002). Nonetheless, the quantitative turn, and its conception of space as a geometrical surface on which human relationships are organized and played out, did change how many of these geographers conceived the notions of space and place.

**Harvey’s explanation in geography**

Despite the rapid growth of quantitative geography throughout the 1960s, as noted, it largely operated in a philosophical vacuum: it focused on methodological form, not the deeper epistemological structure of knowledge production (Gregory, 1978). David Harvey’s book *Explanation in Geography* (1969) was a milestone. Harvey’s key observation of how and why geography had been restructured was that this reordering was based on the discourses that sought to provide a foundation for the discipline’s methodologies. The term that can effectively be called a spatial science drew on the philosophies of a coherent science (1973) himself to construct a coherent science. For Harvey, one of the central issues was the development of a formal philosophy rather than the development of a formal science.
(1969) was a milestone text for the discipline. Harvey’s key observation was that until that point geographers had rarely examined questions of how and why geographical knowledge was produced. And no one had tried to forward a robust and theoretically rigorous methodological (rather than philosophical) base for the discipline. Harvey’s text thus sought to provide such a base by explicitly acknowledging the importance of philosophy to geographical enquiry. In particular he drew on the philosophy of science (which can effectively be translated as positivism despite the fact that Harvey never uses the term) to construct a theoretically sound ontology and epistemology—presented as a coherent scientific methodology. As Harvey (1973) himself later acknowledged (see Chapter 9), however, wider philosophical issues were skirted as his aim was to concentrate on formalizing methodology using philosophy rather than philosophy per se.

**Spatial science as implicit positivism**

While Harvey’s text was enormously influential, providing an initial, theoretically robust ontological and epistemological base for spatial science, it is fair to say that most geographers employing the scientific method have subsequently paid little attention to its philosophical underpinnings. As Hill (1981) notes, positivism implicitly underpins much spatial science work, in that while research seeks to determine casual relationships and spatial laws through statistical analysis and geographical modelling, there is little explicit appreciation or engagement with positivism or other philosophies. As such, while there is the adoption of a scientific method and the use of terms such as law, model, theory and hypothesis, these are often used without an appreciation of what they actually mean or constitute (Hill, 1981; Johnston, 1986). Such research forms a major part of the discipline today, despite criticisms levelled at its positivistic underpinnings. For example, nearly all GIS and geocomputational research is practised as spatial science, although it is fair to say that much of it has actually continued the tradition of empiricism; wherein facts are allowed to ‘speak for themselves’ and are not subject to the rigours of spatial analysis through statistical testing (for example, most mapping work where the maps are allowed to speak for themselves); it is also increasingly rare to see hypotheses stated and then tested. This is not to say that all *quantitative* geography is implicitly positivist (or empiricist). In fact much is not. Indeed quantitative geography refers to the geographical inquiry that uses quantitative data, and such data can be interrogated from a number of ontological and epistemological positions (it is important never to conflate data type with a philosophical approach).

**Criticism and Challenges to Positivist Geography**

The period of transformation in geography’s method opened the way for a sustained period of reflection on the ontology, epistemology and ideology of geographical inquiry from the late 1960s onwards. This coincided with a period of large social unrest in many western countries when many geographers were questioning the relevance and usefulness of the discipline for engaging with and providing practical and political solutions. Consequently, numerous geographers started to question the use and appropriateness of the scientific method and its new, philosophical base of positivism from a number of perspectives. It is important to note here that many of these critiques were not of using and analysing quantitative data *per se*, but rather of the positivist approach to analysing such data; it was a critique of ontology, epistemology, method and ideology, not data type.

The critiques of positivistic geography came from many quarters. For some, such as
Robert Sack (1980), positivist geography was a form of spatial fetishism, focusing on the spatial at the expense of everything else. Spatial science represented a spatial separatist position, decoupling space from time and matter, which he argued meant that it had little analytical value: determining spatial patterns would not tell us why such patterns exist or why they might change over time because the approach fails to take account of social and political process.

Marxist and radical critiques developed the latter point. By rejecting issues such as politics and religion and trying to explain the world through observable facts, radical critics noted that spatial science was limited to certain kinds of questions and was further limited in its ability to answer them. It treated people as if they were all rational beings devoid of irrationality, ideology and history, who made sensible and logical decisions. It therefore modelled the world on the basis that people live or locate their factories and so on in places that minimize or maximize certain economic or social benefits. Critics argued that individuals and society are much more complex, with this complexity being impossible to capture in simple models and laws. As a consequence, Harvey, in a noted turnaround, condemned positivist geography just a few years after writing its ‘bible’: there is ‘a clear disparity between the sophisticated theoretical and methodological framework we are using and our ability to say anything meaningful about events as they unfold around us’ (1973: 128). For Harvey, spatial science could say little about issues such as class divisions, Third World debt, geopolitical tensions and ecological problems because it was incapable of asking and answering the questions needed to interrogate them. Moreover, it was noted that positivist geography lacked a normative function in that it could seek to detail what is and forecast what will be, but could give no insight into what should be (Chisholm, 1971). For Harvey and others, the only way to address such issues was to turn to radical theories such as Marxism which sought to uncover the capitalist structures that underpinned social and economic inequalities and regulated everyday life, and to transform such structures into a more emancipatory system.

Accompanying these radical critiques, from the early 1970s, humanist geographers (see also Chapter 3) similarly attacked positivism with regards to its propensity to reduce people to abstract, rational subjects and its rejection of metaphysical questions (Buttimer, 1976; Guelke, 1974; Tuan, 1976). In effect it was argued that spatial science is peopleless in the sense that it did not acknowledge people’s beliefs, values, opinions and feelings and so on, and their role in shaping everyday geographies. Clearly, individuals are complex beings that do not necessarily behave in ways that are easy to model. Humanist geographers thus proposed the adoption of geographical enquiry that was sensitive to capturing the complex lives of people through in-depth, qualitative studies.

In addition, both radical and humanist critics questioned the extent to which spatial scientists are objective and neutral observers of the world, contending that it is impossible (and in the case of radicals undesirable) to occupy such a position. Geographers, it was argued, are participants in the world, with their own personal views and politics, not privileged observers who could shed these values while undertaking their research (Gregory, 1978). At the very least, researchers make decisions over what they study and the questions they wish to ask, and these are not value-free choices.

This argument was supplemented by feminist geographers such as Domosh (1991), Rose (1993) and McDowell (1992) who argued that spatial science was underpinned by a masculinist rationality (see also Chapter 4). That is, positivism was defined by man’s quest for a god’s-eye view of the world, one which was universal, ‘orderly, rational, quantifiable, predictable, abstract and Wise, 1993: 6) ‘can separate hunches, values, past thought are active objective’ (Rose, geographical enquirers and become power relations w and the geographer reflexive of their practices and influence knowledge. In other words, give up the pretense create a master, world and accept be partial and situational. What this means for geographers is to view geography as a viable space.

In turn, this fits into a wider critique between feminist and scientific science in a geography (1994, that in turn helps Pickles, 1995) to critical approaches and early 2000s. Criticists, postmodernist theories to rethink spatial science (see Harvey, 2003). In it to reposition questioning, providing it with a topographical framework is more contemporary and critical of spatial to address questions or was unable to ta

**Positivist Geography**

Despite the critique, work underpinned
as to turn to radicalism which sought to structures that underlie inequalities and to transform such manipulatory system. Se radical critiques, humanist geographers rarely attacked positivist propensity to reduce moral subjects and its questions (Buttimer, in, 1976). In effect it science was peopleless and not acknowledge emotions, feelings and so during everyday geographers are complex beings as in ways that are stic geographers thus geographical enquiry capturing the complex in-depth, qualitative and humanist (to which spatial and neutral observers that it is impossible (locally undesirable) to Geographers, it was in the world, with us and politics, not so could these thing their research very least, researchers at they study and the risk, and these are not supplemented by has Domosh (1991). Dowell (1992) who was underpinned by (see also Chapter 4). Defined by man’s quest he world, one which rational, quantifiable, predictable, abstract, and theoretical’ (Stanley and Wise, 1993: 66) and in which the knower ‘can separate himself from his body, emotions, values, past and so on, so that he and his thought are autonomous, context-free and objective’ (Rose, 1993: 7). They argued that geographical enquiry had to reject such rationality and become much more sensitive to power relations within the research process, and the geographers had to be more self-reflexive of their positionality, supposed expertise, and influence on the production of knowledge. In other words, geographers had to give up the pretense that they could necessarily create a master, universal knowledge of the world and accept that knowledge will always be partial and situated (from a certain perspective). What this meant in practice was that feminist geographers largely dismissed quantitative geography as a viable means of feminist praxis.

In turn, this feminist critique opened the door to a wider debate on the relationship between feminism, epistemology and spatial science in a special forum of Professional Geographer (1994: ‘Should Women Count?’), that in turn helped (alongside texts such as Pickles, 1995) to fuel the development of critical approaches to GIS in the late 1990s and early 2000s. Critical GIS draws off feminist, postmodern and poststructuralist theories to rethink the modus operandi of spatial science (see Curry, 1998; Kwan, 2002; Harvey, 2003). In many senses it is an attempt to reposition quantitative geography by providing it with a radically different philosophical framework from positivism, one that is more contemporary and robust to traditional criticisms of spatial science and that enables it to address questions that previously it avoided or was unable to tackle.

Positivist Geography Today

Despite the criticism levelled at geographical work underpinned by positivist reasoning, implicit positivism remains strong within human geography. A very large number of geographers argue that they are scientists, employ scientific principles and reasoning, and seek laws or mathematical models that purport to explain the geographical world. However, few seemingly give much thought to the philosophical underpinnings of their scientific method or philosophical debate and critique in general. This leaves much spatial science (and by association, quantitative geography) with relatively weak and unstable philosophical underpinnings (much of it backsliding into empiricism) and vulnerable to theoretic critique and challenge for which it has little response. This is not to say that all spatial science lacks theory; rather it lacks a fundamental and robust ontological, epistemological and ideological base. It also does not mean that spatial science is not useful or valuable within certain limited parameters. The work of spatial scientists clearly does have utility in addressing both fundamental scientific questions and ‘real-world’ practical problems and therefore has academic merit and worth (and it most definitively has utility in the eyes of policy-makers and businesses). However, by ignoring wider philosophical debate spatial scientists often fail to make a robust case for their approach to fellow geographers. As a consequence, many are seduced by the criticisms levelled at positivism and quantification more broadly, and become suspicious and wary of such research. Rather than tackle these criticisms, spatial science increasingly relies on the commercial and policy cache of GIS to make implicitly positivistic geography sustainable. As the debates in GIS science illustrate, however, the implicit positivism underpinning GIS use is open to challenge, with an acknowledgment that the employment of the scientific method can be practiced from more critical perspectives. What might usefully transpire in the long term then is the development of spatial science underpinned by
more critical philosophies, with a move away from or reworking of implicit positivism. That said, given the demand for GIS and quantitative geography in the public and private sector, it is likely that unreconstructed, positivistic geography is secure for the foreseeable future.
